### Abstract

- 2 Background. Colorectal cancer (CRC) is a growing health concern with the majority of the
- 3 risk for developing disease being due to environmental factors. The microbiota is one of these
- 4 environmental factors with certain bacterial community members being associated with CRC, while
- other taxa are associated to colons without tumors. Some of the taxa associated to colons without
- tumors can use fiber to produce short-chain fatty acids (SCFAs) that can inhibit tumor growth in
- 7 model systems. However, the data supporting the importance of SCFAs in human CRC is less
- 8 certain. Here, we test the hypothesis that SCFA concentrations are different in individuals with
- 9 colorectal tumors.
- Methods. We analyzed a cross-sectional (n=490) and longitudinal pre- and post-treatment (n=67)
- group for their concentrations of acetate, butyrate, and propionate. Analysis also included tumor
- classification models using Random Forest, imputed gene relative abundance with PICRUSt, and
- metagenomic sequencing on a subset (n=85) of the total cross-sectional group.
- Results. No difference in SCFA concentrations were found between individuals without tumors and
- patients with adenomas or carcinomas (P-value > 0.15). There was no difference in classification
- 6 models with or without SCFAs in their ability to predict patients with adenomas or carcinomas
- versus individuals without tumors (P-value > 0.05). Using metagenomic sequencing, there was
- also no difference in genes involved with SCFA synthesis between individuals without tumors and
- patients with adenomas or carcinomas (P-value > 0.70).
- <sup>20</sup> Conclusions. Although our data does not support the hypothesis that SCFAs are different in
- 21 individuals that have colorectal tumors, there may be context specific scenarios where SCFAs may
- 22 still be beneficial for treatment of CRC. Alternatively, there may be other mechanisms that have not
- been thoroughly investigated that are more important to the development of human CRC.

### 4 Introduction

Colorectal cancer (CRC) is currently the third highest cancer-related cause of death within the US (1, 2). Although there is a genetic component to the disease, the environment is attributed to being a larger risk factor for CRC (3). These environmental risk factors include but are not limited to smoking cigarettes, diet, and the microbiota (4–6). Many of these environmental risk factors are capable of being modified, and this has lead to the investigation of how the microbiota may exacerbate or cause tumorigensis (7–9) and whether the bacterial community is altered (10, 11). Multiple reports in case/control studies have identified bacterial taxa commonly associated with individuals without tumors to be decreased in patients with carcinoma tumors (11–13). Many of these taxa within individuals without tumors actively produce short-chain fatty acids (SCFAs) from fiber that are a part of our general diet (14). The most extensively studied of these SCFAs are acetate, butyrate, and propionate (15). Overall, the specific bacterial taxa of the microbiota that create SCFAs are an attractive target to modulate the risk of CRC.

Specific SCFAs, like butyrate, have shown positive results for CRC treatment within model systems
(16). Butyrate has been shown to inhibit cancer cell growth in *in vitro* systems (17). Additionally,
supplementation with food sources that bacteria use to create these SCFAs may also be able to
confer beneficial effects. For example, fiber supplementation in mouse models of CRC caused an
overall reduction in tumor burden while also increasing SCFA concentrations (18). Although these
model systems provide important preliminary evidence towards the ability of SCFAs to reduce and
treat tumors, the studies reporting benefit in humans has been less convincing.

There is a lack of evidence on the benefit of increasing SCFA concentrations to protect against CRC in human populations. The initial case/control studies that investigated SCFA concentrations in CRC found that patients with carcinomas had lower concentrations of acetate, butyrate, and propionate versus either patients with adenomas or individuals without colon tumors (19). Although this would argue that increasing SCFA concentrations could be protective against tumorigenesis, fiber supplementation in randomized controlled trials have consistently failed to protect against tumor recurrence (20). These findings would argue against the utility of treatments that aim to use SCFAs to reduce or protect against tumorigenesis. Given the lack of clear evidence in human

studies of the benefit of SCFAs in CRC, there is a need for more investigation into this area.

Our study fills some of the current gaps in the literature that relate to the study of SCFAs and CRC in human populations. Specifically, it tests previous case/control findings on SCFA concentrations in individuals with and without tumors. We also test previous suggestions that there is a continuous reduction in SCFA concentrations as tumor severity increases by increasing the number of patients with adenomas in our study. Additionally, we build upon these observations and assesses the utility of using SCFAs and Operational Taxonomic Units (OTUs) as a risk stratification tool of colorectal tumors (adenoma or carcinoma). Collectively, this study provides important information on the replicability of previous findings in humans by extensively studying how SCFAs are associated with colorectal tumors.

To accomplish this task we directly measured the concentration of acetate, butyrate, and propionate within fecal samples for two different groups. The first group had a sample obtained at a single 63 cross sectional point in time while the second group had samples obtained before (pre-) and 64 after (post-)treatment for colorectal tumors. Additionally, we (i) assessed the affect adding SCFA concentrations to OTU data had on classification of patients with adenoma or carcinoma using the 66 Random Forest algorithm (21), (ii) used PICRUSt (22) and metagenomic sequencing to assess 67 the presence of genes involved in SCFA synthesis, and (iii) analyzed how well 16S rRNA gene sequencing predicts SCFA concentrations. This investigation provides additional information as to whether SCFAs are decreased in patients with colorectal tumors and provides context as to 70 whether targeting taxa to increase SCFA concentrations is a viable option to protect against colon 71 tumorigenesis.

### 73 Results

Decreased SCFA concentrations are not associated with tumors. We used high-performance liquid chromatography (HPLC) to measure acetate, butyrate, and propionate concentrations of frozen fecal samples from 490 individuals at a cross-sectional point in time. There was no difference between individuals without colon tumors (n=172) and patients with either an adenoma (n=198) or carcinoma (n=120) for any of the SCFAs measured after multiple comparison correction (P-value > 0.15) [Figure 1A - 1C]. We next measured the concentration of SCFAs in 67 patients with an adenoma (n=41) or carcinoma (n=26) in which we had pre- and post-treatment fecal samples. Although there was a general trend for increasing acetate, butyrate, and propionate concentrations after treatment for tumors, there was no significant difference pre- and post-treatment for patients with adenomas (P-value > 0.20) or carcinomas (P-value > 0.80) [Figure 1D - 1F].

## <sup>84</sup> Changes in genes for enzymes involved in SCFA synthesis are not associated with tumors.

Using a list of specific genes that are important for the synthesis of SCFAs [Table S1], we looked for differences in gene abundance between individuals without colon tumors and patients with adenomas or carcinomas. First, using imputed gene relative abundance based on 16S rRNA gene 87 sequencing we found no difference in any of the genes involved with acetate, butyrate, or propionate synthesis (P-value > 0.90) [Table S2]. This similarity between groups is highlighted by visualizing genes important in butyrate synthesis [Figure 2A]. Using a paired Wilcoxon rank-sum test, there also 90 was no difference in imputed gene relative abundance between pre- and post-treatment samples 91 for any genes involved with SCFA synthesis (P-value > 0.70) [Table S3]. Next, we took a subset of these 490 fecal samples (n=85) and used metagenomic sequencing to confirm these results. Like the imputed gene results, metagenomic analysis found that there was no difference in any of the genes involved in SCFA synthesis between individuals without colon tumors (n=29) and patients with adenoma (n=28) or carcinoma (n=28) (P-value > 0.70) [Table S4]. This lack of difference can be highlighted when we visualize the results for butyrate kinase [Figure 2B]. These observations 97 provide evidence that gene prevalence for enzymes involved in SCFA synthesis does not change due to colorectal tumors.

Total significant positive correlations between OTU relative abundance and SCFA

concentration were similar for individuals without tumors and patients with adenomas or 101 carcinomas. Having found no difference between individuals without tumors and patients with 102 adenomas or carcinomas in SCFA concentrations or genes coding for enzymes involved with 103 SCFA synthesis, we next investigated if specific OTUs correlated with SCFA concentrations. Using 104 Spearmans rho we found that the majority of significant OTU correlations were to taxa from 105 Clostridiales, Lachnospiraceae, and Ruminococcaceae [Figure 3 & Table S5]. A similar pattern 106 was observed when using high/low SCFA groups based on the overall median concentration for 107 that specific SCFA [Figure S1 & Table S6]. There was a noticeablely higher number of significant 108 negative correlations associated with patients with adenomas for all SCFAs tested [Figure 3]. 109 In particular, OTUs from the Ruminococcaceae family had the largest share of these negative 110 correlations within patients with adenomas [Figure 3]. Although patients with adenomas had more 111 positive correlations between OTUs and SCFA concentrations, their total number was more similar 112 to individuals without tumors or patients with carcinomas versus the analogous comparison for the 113 number of negative correlations [Figure 3]. The number of positive correlations between OTUs and 114 SCFA concentrations was similar between individuals without tumors and patients with a carcinoma [Figure 3]. Overall, these results suggest that the resident taxa that may change the most due 116 to colon tumors may not be ones that are responsible for the production of acetate, butyrate, or 117 propionate. 118

SCFA concentrations do not replace important Clostridiales, Lachnospiraceae, and 119 Ruminococcaceae OTUs in Random Forest models built to classify tumors. 120 concentrations could improve prediction of tumors based on specific bacterial community structures. 121 Our OTU data can be used in combination with SCFAs to assess whether there is a community dependent context to SCFA classification of tumors. Using the Random Forest algorithm we 123 built models with OTU abundance data or OTU abundances and SCFA concentrations to classify 124 normal versus adenoma and normal versus carcinoma fecal samples. For adenoma and carcinoma models, there was no difference between the median AUC of models with or without SCFA 126 concentrations (P-value > 0.05) [Figure 4A & 4D]. There was little difference between the top 127 10 most important OTUs, as measured by mean decrease in accuracy, in models using SCFA and OTUs versus OTUs only [Figure 4B-C & 4E-F]. The main reason for this was because SCFA 129

concentrations replaced the information gained by specific OTUs rather than add new information to the model [Figure 4B-C]. The SCFA concentrations also only replaced select OTUs with taxonomic classification to *Clostridiales*, *Lachnospiraceae*, and *Ruminococcaceae* with many OTUs within these taxa remaining in the top 10 [Figure 4B & 4C]. In combination with the previous results on taxa correlations, these observations provide additional evidence that the resident taxa within models that classify tumor are not ones associated with acetate, butyrate, or propionate production.

Random Forest models for SCFA concentrations have different top 10 most important OTUs than tumor models. Using OTU data we built Random Forest models to classify either SCFA concentration or higher/lower than median SCFA concentrations. Overall, OTU data had a reasonable ability to classify both SCFA concentrations and high/low SCFA groups [Figure 5A & S2A]. However, these models tended to be over fit, suggesting that rarer taxa may be important for this classification [Figure 5A & S2A]. Additionally, there were differences in accuracy for both model types based on whether the individual had no tumors, an adenoma, or a carcinoma [Figure 5B & S2B]. There also was minimal overlap between these SCFA classification model's most important OTUs and those used to classify patients with adenoma or carcinoma tumors [Figure 4B-C, 4E-F, 5C-E, and S2C-E]. The only OTU that did overlap between the models was OTU00167 (Clostridiales) [Figure 4B-C, 4E-F, 5C-E, and S2C-E]. Additionally, OTU00167 was in the top 10 most important OTUs for the OTU adenoma model but not in the SCFA and OTU adenoma model while acetate and butyrate concentrations were [Figure 4B-C]. These observations provide further evidence that it is possible to identify specific OTUs associated with higher SCFA concentrations and that these OTUs belong to taxa known to produce acetate, butyrate, and propionate. Although it is possible to identify OTUs associated with SCFA production, our results do not support the hypothesis that SCFA concentration or OTUs associated with their production are different between individuals with no tumors and patients with adenomas or carcinomas.

### 154 Discussion

The observations from this study do not support the hypothesis that SCFA concentrations are different in individuals with tumors. Whether we directly measured the SCFA concentration or investigated genes associated with their production, no difference could be identified between individuals without tumors and patients with adenomas or carcinomas [Figure 1 & 2]. Although there were differences in the number of significant correlations between SCFA concentration and OTU relative abundance based on whether individuals did not have tumors, had an adenoma, or had a carcinoma, SCFA concentrations did not provide increased model accuracy for tumor classification [Figure 3-4 & S1]. Instead, SCFA concentrations provided similar information to what specific OTUs were already providing to the tumor classification models [Figure 4]. Additionally, when models using OTU relative abundance to classify SCFA concentrations were assessed, the OTUs that classified to *Clostridiales*, *Lachnospiraceae*, and *Ruminococcaceae* were not the same as the OTUs that classified to these taxa in the tumor models [Figure 4-5]. Collectively, our observations suggest that resident taxa from *Clostridiales*, *Lachnospiraceae*, and *Ruminococcaceae*, that are different between individuals without tumors and patients with adenomas or carinomas, are not that same as those involved with SCFA production.

Much of the previous research on SCFA benefit to human CRC has been illustrated in model systems (16). Many SCFAs are produced through the breakdown of fiber (14) and a recent study in mice found that fiber supplementation increased SCFA concentrations and decreased tumor burden (18). Additionally, SCFAs such as butyrate can inhibit tumor growth in *in vitro* experiments (17). Yet, observations in humans has been mixed. Previous case/control studies found associations with lower SCFA concentrations in individuals with carcinoma tumors (19). However, individual randomized controlled trials and a recent meta-analysis on fiber supplementation to prevent tumor recurrence has found no benefit (20, 23). Our results align with what has been reported in randomized-controlled trials, that SCFAs do not provide general protection against colorectal tumors. It is possible though that there are specific instances where SCFAs may be beneficial. 

One limitation of current research into the effect of SCFAs in CRC has been that all tumors are treated as the same type. However, there are known differences in the types of mutations that

occur (24) and treating all tumors as equal may actually hide any benefit that could be found in 182 specific subsets of individuals. Similar to the idea of specific immunotherapy for specific tumors (25), SCFAs may have beneficial effects for specific types of colorectal tumors. Future research will 184 need to test if this is a valid hypothesis. Another limitation is that a fecal sample may not be an ideal 185 type of biospecimen and that the effect SCFAs have on tumorigenesis is only detected in the colon. 186 However, most in vivo studies as well as human studies have used fecal material in their analysis 187 (18, 19). Additionally, studies that measure SCFA changes after fiber supplementation use fecal 188 material to track these responses (26). Although there are limitations with the current research on 189 SCFAs and colorectal tumors, our observations along with the randomized controlled trials on fiber supplementation in tumor recurrence (20) provide evidence that these specific metabolites may 191 not be protective. Yet, taxa that are associated with SCFA production are consistently higher in 192 indivdiuals without colon tumors than patients with carcinomas (10, 11, 27).

The potential protection against colorectal cancers may not be from SCFAs even though taxa 194 associated with their production are higher in individuals without tumors versus patients with 195 carcinomas (10, 11, 27). Protection could be via a different pathway and by extension other 196 metabolites that have not been extensively studied. Alternatively, protection may not occur via a 197 metabolite but instead through niche exclusion of mouth-associated microbes (e.g. Fusobacterium, 198 Porphyromonas, Parvimonas, Peptostreptococcus (6, 12, 13)). The idea of niche exclusion is similar to how the community protects against Clostridium difficile infection (28) with chronic inflammation 200 replacing the role of antibiotics. Although we did not find lower concentrations of SCFAs associated 201 with colorectal tumors, we think that there are many exciting new avenues to explore because of 202 these results.

## 204 Conclusions

Our observations found no difference in SCFA concentration, their utility as a classification tool, or for genes of enzymes involved in SCFA synthesis between individuals without colon tumors and patients with either adenoma or carcinoma tumors. Although these results are different than other reports in the literature, they do align with the randomized controlled trials that have tested fiber use in preventing colorectal tumor recurrence. Overall, these results suggest that the SCFAs typically produced by resident microbes do not protect against tumor. By focusing on other types mechanisms, the identification of more promising therapeutic options for use in treating colorectal cancer may be found.

### Materials and Methods

224

225

227

228

Study design and sampling. The overall protocol has been described in detail previously (29, 214 30). In brief, this study used fecal samples obtained at either a single cross-sectional time point 215 (n=490) or from before (pre-) and after (post-) treatment of a patient's tumor (n=67). For patients 216 undergoing treatment for their tumor the length of time between their initial and follow up sample 217 ranged from 188 - 546 days. Our use of treatment has been previously defined as encompassing 218 removal of a tumor with or without chemotherapy and radiation (29). Diagnosis of tumor was 219 made by colonoscopic examination and histopathological review of biopsies obtained (29, 30). The University of Michigan Institutional Review Board approved the study and informed consent was 221 obtained from all participants in accordance to the guidelines set out by the Helsinki Declaration. 222

Measuring specific SCFAs. Our protocol for the measurement of acetate, butyrate, and propionate followed a previously published protocol that used a High-Performance Liquid Chromatography (HPLC) machine (26). The following changes to this protocol included the use of frozen fecal samples suspended in 1ml of PBS instead of fecal suspensions in DNA Genotek OmniGut tubes, and the use of the actual weight of fecal samples instead of the average weight for SCFA concentration normalizations. These methodological changes did not affect the overall median concentrations of these SCFAs between the two studies (see Table 1 (26) and Figure 1 here).

16s rRNA gene sequencing. The workflow and processing have been previously described (29, 31, 32). The major differences from these previous reports include: the use of version 1.39.5 of the mothur software package and clustering Operational Taxonomic Units (OTUs) at 97% similarity using the OptClust algorithm (33).

Generating imputed metagenomes. The use of PICRUSt version 1.1.2 with the recommended standard operating protocol (22) was used. Briefly, the mothur shared file and metadata was converted into a biom formatted table using the biom convert function, the subsequent biom file was processed with the 'normalize\_by\_copy\_number.py' function, and subsequent imputed metagenomes created using the 'predict\_metagenomes.py' function.

Obtaining Operational Protein Families from metagenomes. A subset of the cross-sectional

group (n=490) containing a total of 85 individuals (normal n=29, adenoma n=28, and carcinoma n=28) was shotgun sequenced on an Illumina HiSeq using 125 bp paired end reads and a previously described method (34). Briefly, the sequences were quality filtered and sequences aligning to the human genome were removed prior to contig assembly with MEGAHIT (35). Open Reading Frames (ORFs) were identified using Prodigal (36), counts generated using Diamond (37), subsequent clustering into Operational Protein Families (OPFs) used mmseq2 (38), and OPF alignment used the KEGG database (39).

Pulling genes involved with SCFA synthesis. Specific genes located near the end of the pathways involved in the synthesis of acetate, butyrate, and propionate were analyzed for any differences between individuals with normal colons and those with tumors. These genes were based on pathways from KEGG as well as previous research (39, 40) and a list can be found in the supplemental material [Table S1].

Random Forest models. The model was first trained on 80% of the data and then tested on the
held out 20% (80/20 split) using the Random Forest algorithm for classification models (21). This
was repeated on 100 different 80/20 splits of the data to generate a reasonable range for the AUC of
the model. The reported AUCs, unless otherwise specified, are for the test sets. The classification
models were built to group normal versus adenoma, normal versus carcinoma, and high versus low
SCFA concentrations.

Statistical analysis workflow. All analysis was performed using the statistical language R (41). 258 Generally, a Kruskal-Walis rank sum test with a Dunn's post-hoc test was used to assess differences 259 between the groups used. Where appropriate Benjamini-Hochberg was used to correct for multiple comparisons (42). First, we assessed differences in SCFA concentrations measured by HPLC 261 between individuals with normal colons and patients with tumors (adenoma or carcinoma). We 262 then analyzed whether SCFA concentrations changed in patients with an adenoma or carcinoma pre- versus post-treatment. Next, we assessed whether OTUs alone or OTUs and SCFAs were 264 better able to classify individuals with and without tumor using Random Forest models. Next, the 265 imputed gene counts of important mediators of SCFA synthesis was tested. Additionally, the counts 266 generated for OPFs that matched important genes involved with SCFA creation were analyzed.

- <sup>268</sup> Finally, models to classify high or low SCFA concentration based on the median of each SCFA and
- 16S rRNA gene sequencing data was created using the Random Forest algorithm.

- Figure 1. No change in SCFA measurements was observed between normal, adenoma, 398 and carcinoma individuals using HPLC. Acetate concentrations in fecal samples of individuals 399 without colon tumors, adenomas, and carcinomas (A). Butyrate concentrations in fecal samples 400 of individuals without colon tumors, adenomas, and carcinomas (B). Propionate concentrations 401 in fecal samples of individuals without colon tumors, adenomas, and carcinomas (C). The black 402 lines indicate the median SCFA concentration. Acetate concentrations in fecal samples before 403 and after treatment for adenoma (yellow) and carcinoma (red) (D). Butyrate concentrations in fecal 404 samples before and after treatment for adenoma (yellow) and carcinoma (red) (E). Propionate 405 concentrations in fecal samples before and after treatment for adenoma (yellow) and carcinoma (red) (F). The black dots and lines represent the median change in SCFA concentration. 407
- Figure 2. No change in butyrate producing genes identified between normal, adenoma, and carcinoma individuals. Imputed gene relative abundance of important butyrate pathway genes using PICRUSt (A). Counts per million (corrected for size and number of contigs in an OPF) for the Butyrate Kinase gene (B). The other butyrate pathway genes from the PICRUSt analysis did not align to any of the OPFs in the metagenome analysis.
- Figure 3. Patients with adenomas had the higest number of significant negative correlations between OTU relative abundance and SCFA concentration. Colors denote the family or lowest taxonomic ID that an OTU classified to. Fewer significant positive correlations were observed overall. Additionally, the differences in the number of significant positive correlations between patients with adenomas versus individuals without tumors (normal) and patients with carcinomas was not as pronounced as the number of significant negative correlations.
- Figure 4. SCFA concentrations do not improve OTU-based Random Forest models. The
  area under the curve of 100 different 80/20 split OTU-based normal versus adenoma 10-fold CV
  models with and without SCFAs (A). The top 10 most important OTUs or SCFAs in the SCFA
  and OTU adenoma model (B). The top 10 most important OTUs in the OTU adenoma model (C).
  The area under the curve of 100 different 80/20 OTU-based normal versus carcinoma 10-fold CV
  models with and without SCFAs (D). The top 10 most important OTUs or SCFAs in the SCFA and
  OTU carcinoma model (E). The top 10 most important OTUs in the OTU carcinoma model (F). For

(A) and (D) the black line represents the median AUC. The dotted line highlights an AUC of 0.5.

Figure 5. OTU-based regression Random Forest models of SCFA concentrations. The train and test correlation between actual and predicted values from 100 different 80/20 split OTU-based models with 10-fold CV using regression Random Forest (A). The model accuracy of predicted SCFA concentrations differed between individuals without tumors, patients with adenomas, and patients with carcinomas. Generally, patients with carcinomas had predicted concentrations closest to their actual measured concentration (B). The top 10 OTUs based on mean decrease in accuracy (MDA) for each SCFA model, colored by their lowest taxonomic identification (C).

- Figure S1. Patients with adenomas had the higest number of significant differences in
  OTU relative abundance between high/low SCFA groups. Colors denote the family or lowest
  taxonomic ID that an OTU classified to. Fewer significant OTUs were observed in individuals without
  tumors (normal) and patients with carcinomas versus patients with adenomas.
- Figure S2. OTU-based classification Random Forest models of high/low SCFA groups
  based on overall SCFA median concentration. The train and test results of 100 different
  80/20 split OTU-based models with 10-fold CV based on higher or lower than the median SCFA
  concentration using classification Random Forest (A). The model accuracy of predicted high/low
  SCFA groups differed between individuals without tumors, patients with adenomas, and patients
  with carcinomas. Patients with adenomas consistently had the best classification accuracy (B). The
  top 10 OTUs based on mean decrease in accuracy (MDA) for each SCFA model, colored by their
  lowest taxonomic identification (C).
